Sinonasal Ewing Sarcoma: A Case Report and Literature Review

Jonathan K Lin, MD, MBA; Jonathan Liang, MD

ABSTRACT

Introduction: Ewing sarcoma (ES) of the sinonasal tract and associated primitive neuroectodermal tumors are rare. To our knowledge, only 10 case reports of sinonasal ES of the nose or paranasal sinuses have been reported. Furthermore, there has been only 1 case of sinonasal ES arising from the middle turbinate. Recommended management of sinonasal ES stems from the management of its osseous counterpart, ES, but treatment with surgery, radiotherapy, and chemotherapy is varied. Five-year survival rates vary from 21% to 70%, with the lower rates representing patients presenting with metastatic disease.

Case Presentation: A 26-year-old man presented with persistent left-sided nasal obstruction. Endoscopy demonstrated a friable mass in the left nasal cavity originating from the middle turbinate with extension into the nasopharynx, confirmed with computed tomography and magnetic resonance imaging. There was no evidence of metastatic disease on positron emission tomography-computed tomography. Histopathologic results were consistent with sinonasal ES. The result of fluorescent in situ hybridization was positive for the EWS gene translocation. A multidisciplinary tumor board evaluated the patient. The patient then underwent neoadjuvant chemotherapy, followed by definitive endoscopic surgical resection and postoperative radiotherapy.

Discussion: Our literature review found more involvement of the maxillary and ethmoid sinuses compared with the nasal cavity, and that the role of radiation and surgical approach was varied. ES of the sinonasal tract is a rare entity with high mortality, but few standardized treatment protocols exist. Further study and evidence-based treatment protocols are needed. This article outlines the role of relevant imaging, a multidisciplinary team approach, and the optimal timing of surgery, chemotherapy, and radiation.

INTRODUCTION

Ewing sarcoma (ES) is a rare and aggressive tumor that typically involves the long bones of the extremities (skeletal form). The less common extraskeletal form involves soft tissues and rarely manifests in the head and neck region. Genetically, the abnormal t(11;22) chromosome translocation is a hallmark of diagnosis. ES of the nose or paranasal sinuses is a rare subset of ES, with treatment consisting primarily of chemotherapy followed by surgery and/or radiotherapy.

CASE PRESENTATION

Presenting Concerns

A 26-year-old man presented to the Head and Neck Surgery Clinic with persistent left-sided nasal obstruction. Flexible nasal endoscopy showed a left-sided friable mass originating from the middle turbinate and extending into the nasopharynx. This endoscopic image is not available, but a very similar endoscopic image, performed later in our patient’s course of treatment, is shown in Figure 1. The patient was treated for sinusitis and nasal polyps with oral antibiotics, oral corticosteroids, a steroid nasal spray, and an oral antihistamine. Computed tomography (CT) was scheduled for 1 month after completion of treatment. The CT scan showed a soft-tissue mass in the left posterior nasal cavity.

Therapeutic Intervention and Treatment

After being lost to follow-up for 3 months, the patient was seen again, and plans were made for a biopsy of the lesion. The biopsy specimen confirmed the diagnosis of ES. Magnetic resonance imaging (MRI) and positron-emission tomography were then performed for staging and treatment planning. Figure 2 shows the extent of the mass as seen on the initial MRI. Pathologic evaluation on hematoxylin–eosin staining revealed cords of tissue infiltrated by cords and nests of neoplasm with small round blue cell features. Scattered mitotic and apoptotic

Figure 1. Rigid nasal endoscopy image from study performed at halfway point of chemotherapy. A purple friable mass is seen extending from the left posterior lateral nasal wall between the middle and inferior turbinates in the sphenoid recess. Biopsy specimen showed persistent disease.

Figure 2. Coronal, T2-weighted magnetic resonance image of the head after contrast enhancement, showing a 4.5-cm enhancing mass centered in the left posterior nasal cavity with extension into the nasopharynx, consistent with Ewing sarcoma/primitive neuroectodermal tumor.
figures were seen (Figures 3 and 4). Immunohistochemistry showed positive staining for CD99 antigen (Figure 5). Findings were supportive of ES/primitive neuroectodermal tumor (PNET). Fluorescent in situ hybridization testing was positive for the t(11;22) translocation associated with the EWS gene in 89% of the cells. Flow cytometry revealed atypical cells that were not further characterized.

The patient’s case was presented to our institution’s multidisciplinary tumor board. A referral was made to a hematologist-oncologist, who recommended chemotherapy. The result of a bone marrow biopsy performed before chemotherapy did not show any evidence of metastatic disease via pathology or fluorescent in situ hybridization analysis.

One month after diagnosis, our patient started chemotherapy with a regimen of vincristine, doxorubicin, and cyclophosphamide alternating with cycles of ifosfamide and etoposide. He underwent 4 cycles of this regimen. Repeated positron-emission tomography/CT performed 2 months after the start of chemotherapy showed resolution of the previous hypermetabolic left-sided posterior nasopharyngeal mass, without fluorodeoxyglucose-avid metastatic disease. However, there was a persistent nonfluorodeoxyglucose-avid, ovoid, soft-tissue density that on repeat biopsy showed persistent disease. The findings during this biopsy are shown in Figure 1. Repeat MRI showed a small (8 mm × 14 mm × 18 mm) enhancing soft-tissue mass in the location of the original lesion. After the patient was evaluated by a radiation oncologist, his case was again presented to our regional tumor board. The decision was made to perform surgical resection with another round of chemotherapy and possible radiation therapy pending surgical margins and final pathology.

The patient was taken to the operating room for endoscopic surgery and removal of the mass centered along the left lateral nasal wall. Surgery was conducted with imaging guidance. A septoplasty was performed for improved exposure. The specimen was resected en bloc, with good exposure. Margins included the posterior antrostomy, inferior turbinate, anterior lateral nasal wall, and uncinate and ethmoid bulla.

Follow-up and Outcomes

All intraoperative margins were negative for tumor. Final pathology confirmed residual disease with negative margins and no evidence of lymphovascular or perineural involvement.

The patient healed well postoperatively and continued his original course of chemotherapy. He did not require radiotherapy because of the absence of high-risk features and negative margin status on final pathology. Twelve-month postoperative follow-up showed no evidence of tumor recurrence.

Figure 6 shows a timeline of the case. Our patient gave written, informed consent for inclusion in this report.

DISCUSSION

We describe what we believe is the first reported case of ES originating from the middle turbinate in a young man. By itself, ES is a rare disease, making up only 4% to 6% of all primary bone tumors. Furthermore, ES involves the head and neck region in only 1% to 4% of cases, and tumors with a sinonasal origin form another rare subset. Simons et al describes the difficulty in diagnosis of small round blue cell tumors as well as a systemic approach to aid clinicians. ES is described as part of a family of tumors with neuroectodermal differentiation. More specifically, ES is classified as a peripheral PNET. Immunohistochemistry often narrows the diagnosis greatly. For example, a lesion that is positive for CD99 antigen and vimentin would be either alveolar rhabdomyosarcoma or ES/PNET. Staining for desmin or myogenin would help direct the clinician toward a diagnosis of ES/PNET in the former scenario and alveolar rhabdomyosarcoma in the latter.

Strong membrane-only CD99 positivity would again point toward ES/PNET. Clinical parameters can be of aid as well. Typically ES/PNET presents in patients younger than age 30 years, with men affected more often than women. Molecular analysis is particularly useful if the diagnosis is already narrowed to 2 or 3 entities. For ES, the t(11;22)(q24;q12) translocation corresponding to EWSR1/FLI-1 fusion is often diagnostic and used for confirmation. However, variant translocations are seen in 10% to 15% of ES cases.

After diagnosis of ES is confirmed, additional necessary studies include CT and MRI to help anatomically define the lesion as a baseline before starting treatment as well as for surgical planning purposes should surgery be pursued. Furthermore, positron-emission tomography should be performed to stage the disease and look for evidence of metastatic disease. Previous studies have found a rate of metastatic disease at diagnosis of around 12.5% for ES of the head and neck, and 20% to 30% for ES.
Sinonasal Ewing Sarcoma: A Case Report and Literature Review

26-y-old man with a history of left-sided nasal obstruction and epistaxis.

CT showed left posterior nasal cavity soft-tissue mass.

Lesion biopsied. Standard pathologic evaluation and FISH testing performed. Mass diagnosed as Ewing sarcoma.

MRI and PET scan performed.

Referral to hemato-oncologist. Bone marrow biopsy performed.

Chemotherapy started.

Repeat PET and MRI showed persistent disease.

Surgical resection performed.

Surgical margins in our case, radiation therapy was ultimately avoided, and chemotherapy was given postoperatively only because the patient was in the midst of his chemotherapy protocol when the residual disease was identified.

Previous studies that routinely reported radiation therapy along with chemotherapy as an initial management option primarily included large tumors (> 10 cm). This may be because of decreased access to imaging modalities and health care, a hypothesis outlined by the authors of the largest series to date. As in our case, surgery is often not recommended as the first-line treatment given the substantial morbidity associated with large head and neck tumor resection. However, with the earlier detection of tumors and the development of advanced endoscopic techniques, treatment patterns may shift. Given the rarity of this disease, no uniform follow-up regimen is currently outlined by the authors of the largest series to date. As in our case, surgery is often not recommended as the first-line treatment given the substantial morbidity associated with large head and neck tumor resection. However, with the earlier detection of tumors and the development of advanced endoscopic techniques, treatment patterns may shift. Given the rarity of this disease, no uniform follow-up regimen is currently recommended. Previous authors have suggested regular follow-up every 3 months for the first year, every 6 months for the second year, and then yearly thereafter. Our patient followed a similar follow-up plan, with imaging as needed on the basis of clinical suspicion of tumor recurrence. Of course, any follow-up plan will depend on the aggressiveness of the tumor and patient or clinician limitations.

CONCLUSION

ES of the sinonasal tract is a rare entity that has a high mortality and for which few standardized treatment protocols exist. This report outlines the role of relevant imaging, pathologic, and cytogenetic studies; the importance of a multidisciplinary team; the timing of surgery; and a proposed chemotherapy regimen. Our patient received chemotherapy up front, followed by surgical salvage therapy for residual disease and completion of chemotherapy without evidence of recurrence at 12-month follow-up. In our literature review, we underscore the gaps in the current research literature, including the role of radiation therapy, various surgical options, and the ideal follow-up period.
